

DESCRIPTION**VEHICLE AND CONTROL METHOD OF VEHICLE SLIP-DOWN VELOCITY****5 Technical Field**

The present invention relates to a vehicle and a control method of the vehicle. More specifically the invention pertains to a vehicle equipped with a power output device that is capable of outputting a driving force to a drive shaft linked
10 with drive wheels, as well as to a control method of a vehicle equipped with a power output device that is capable of outputting a driving force to a drive shaft linked with drive wheels and with a mechanical braking device that is capable of applying a mechanical braking force to the vehicle.

15

Background Art

A proposed electric vehicle controls a motor linked with wheels to stop the vehicle in response to detection of a slip-down of the vehicle on an ascending slope (for example,
20 see Japanese Patent Laid-Open Gazette No. 7-322404). This prior art vehicle specifies a slip-down state of the vehicle when the rotating direction of the motor is reverse to a gearshift position in a forward direction, and regulates the output torque of the motor to stop the vehicle with a slight
25 step-on of an accelerator pedal.

This prior art vehicle, however, can not adequately

respond to the occurrence of a slip on an ascending slope with the road surface of a low μ value. In the case of the occurrence of a slip, the general control restricts the output torque of the motor to reduce the slip. It is thus extremely difficult
5 to prevent a slip-down of the vehicle on the ascending slope by regulating the output torque of the motor.

Disclosure of the Invention

The vehicle and the control method of the vehicle of the
10 invention thus aim to eliminate the drawbacks of the prior art technique and to regulate the velocity of a slip-down of the vehicle while reducing a slip on a road surface with a gradient. The vehicle and the control method of the vehicle of the invention also aim to ensure practically constant drive feeling,
15 regardless of a road surface gradient.

In order to attain at least part of the above and the other related objects, the invention is directed to a vehicle and a control method of the vehicle as discussed below.

A vehicle of the present invention is equipped with a
20 power output device that is capable of outputting a driving force to a drive shaft linked with drive wheels, and the vehicle includes: a mechanical braking device that is capable of applying a mechanical braking force to the vehicle; a slip detection module that detects a slip caused by spin of the drive
25 wheels; a slip-down detection module that detects a slip-down of the vehicle; and a controller that actuates and controls

the power output device to restrict the driving force output to the drive shaft in response to detection of a slip by the slip detection module, while actuating and controlling the mechanical braking device to apply a mechanical braking force to the vehicle in response to detection of a slip-down of the vehicle by the slip-down detection module under restricting the driving force output to the drive shaft.

The vehicle of the invention actuates and controls the power output device to restrict the driving force output to the drive shaft linked with the drive wheels, in response to detection of a slip caused by spin of the drive wheels. In response to detection of a slip-down of the vehicle under restricting the driving force output to the drive shaft, the vehicle of the invention actuates and controls the mechanical braking device to brake the vehicle with a mechanical braking force. This arrangement effectively regulates the velocity of a slip-down of the vehicle under restricting the driving force output to the drive shaft due to the occurrence of a slip on the road surface with a gradient.

The vehicle of the invention may include a running direction setting module that sets a running direction of the vehicle. In the vehicle of the invention, the slip-down detection module may include a reverse run detection module that detects a reverse run of the vehicle in a reverse direction to the running direction of the vehicle set by the running direction setting module, and the controller may actuate and

control the mechanical braking device to apply a mechanical braking force to the vehicle, in response to detection of the reverse run by the reverse run detection module under restricting the driving force output to the drive shaft. In this case, the reverse run detection module may include a vehicle speed sensor that measures a vehicle speed in the reverse direction, and the controller may actuate and control the mechanical braking device to apply a braking force corresponding to the measured vehicle speed in the reverse direction. Further, the controller may actuate and control the mechanical braking device to make the vehicle speed in the reverse direction approach to a preset vehicle speed. This arrangement makes the velocity of the slip-down of the vehicle converge to the preset vehicle speed.

The vehicle of the invention may include a road surface gradient measurement estimation module that either measures or estimates a road surface gradient. In the vehicle of the invention, the controller may actuate and control the mechanical braking device to apply a braking force corresponding to the measured or estimated road surface gradient. This arrangement ensures practically constant drive feeling, regardless of the road surface gradient. In this case, the vehicle of the invention may further include a running direction setting module that sets a running direction of the vehicle. In the vehicle of the invention, the slip-down detection module may include a vehicle speed sensor that

measures a vehicle speed in the reverse direction to the running direction of the vehicle set by the running direction setting module, the road surface gradient measurement estimation module may estimate the road surface gradient according to a relation between an acceleration of the vehicle and the driving force output to the drive shaft, and the controller may actuate and control the mechanical braking device to apply a braking force corresponding to a product of a balancing force, which balances with a force acting in a direction of the slip-down of the vehicle based on the relation between the acceleration of the vehicle and the driving force output to the drive shaft, and a ratio specified according to the measured vehicle speed in the reverse direction. In this case, the controller may actuate and control the mechanical braking device to make the vehicle speed in the reverse direction approach to a preset vehicle speed. This arrangement makes the velocity of the slip-down of the vehicle converge to the preset vehicle speed.

In the vehicle of the invention, the mechanical braking device may include a brake that applies a mechanical braking force to driven wheels, which are different from the drive wheels. This arrangement desirably prevents the braking force output from the mechanical braking device from interfering with the driving force output from the power output device.

A method of the invention is a control method of a vehicle, which is equipped with a power output device that is capable of outputting a driving force to a drive shaft linked with drive

wheels, and with a mechanical braking device that is capable of applying a mechanical braking force to the vehicle, and includes the steps of: (a) detecting a slip caused by spin of the drive wheels; (b) actuating and controlling the power output device to restrict the driving force output to the drive shaft, in response to detection of a slip in the step (a); (c) detecting a slip-down of the vehicle; and (d) actuating and controlling the mechanical braking device to apply a mechanical braking force to the vehicle, in response to detection of a slip-down of the vehicle in the step (c) under restricting the driving force output to the drive shaft in the step (b).

The control method of the vehicle of the invention actuates and controls the power output device to restrict the driving force output to the drive shaft linked with the drive wheels, in response to detection of a slip caused by spin of the drive wheels. In response to detection of a slip-down of the vehicle under restricting the driving force output to the drive shaft, the control method of the invention actuates and controls the mechanical braking device to brake the vehicle with a mechanical braking force. This arrangement effectively regulates the velocity of a slip-down of the vehicle under restricting the driving force output to the drive shaft due to the occurrence of a slip on the road surface with a gradient.

Best Modes of Carrying Out the Invention

20 One mode of carrying out the invention is discussed below as a preferred embodiment. Fig. 1 schematically illustrates the configuration of a vehicle 20 in one embodiment of the invention. As illustrated, the vehicle 20 of the embodiment includes a motor 22 that utilizes a supply of electric power
25 from a battery 26 via an inverter circuit 24 and outputs power to a drive shaft 28, which is mechanically linked with drive

wheels 62a and 62b via a differential gear 29, and a main electronic control unit 70 that controls the whole vehicle.

The motor 22 is a synchronous motor generator functioning as both a motor and a generator. The inverter circuit 24
5 includes multiple switching elements to convert an input of electric power from the battery 26 into an adequate form of electric power for driving the motor 22 and output the converted electric power.

Hydraulic brakes 54a, 54b, 56a, and 56b, which are
10 actuated by means of hydraulic pressure from a brake master cylinder 90, are attached to the drive wheels 62a and 62b and driven wheels 64a and 64b. Activation and control of a brake actuator 52 by a brake electronic control unit (hereafter referred to as brake ECU) 50 regulates the braking torques of
15 the hydraulic brakes 54a, 54b, 56a, and 56b. The brake ECU 50 is constructed as a microprocessor including a CPU, a ROM that stores processing programs, a RAM that temporarily stores data, input and output ports, and a communication port, although not being specifically illustrated. The brake ECU
20 50 receives, via its input port, input signals from various sensors, for example, wheel speeds from wheel speed sensors 34a, 34b, 36a, and 36b that measure rotational speeds of the drive wheels 62a and 62b and the driven wheels 64a and 64b. The brake ECU 50 outputs control signals to the brake actuator
25 52 via its output port. The brake ECU 50 establishes communication with the main electronic control unit 70 via its

communication port to activate and control the brake actuator 52 in response to control signals from the main electronic control unit 70 and to send input data to the main electronic control unit 70 according to the requirements.

5 The main electronic control unit 70 is constructed as a microprocessor including a CPU 72, a ROM 74 that stores processing programs, a RAM 76 that temporarily stores data, non-illustrated input and output ports, and a non-illustrated communication port. The main electronic control unit 70
10 receives, via its input port, various input signals including a rotational position θ_{res} from a rotational position detection sensor 32 (for example, a resolver) that detects the rotational position of the drive shaft 28 (the rotating shaft of the motor 22), a gearshift position SP from a gearshift position sensor
15 82 that detects the current position of a gearshift lever 81, an accelerator opening Acc from an accelerator pedal position sensor 84 that measures a step-on amount of an accelerator pedal 83, a brake pedal position BP from a brake pedal position sensor 86 that measures a step-on amount of a brake pedal 85, a vehicle
20 speed V from a vehicle speed sensor 88, and a road surface gradient θ_{gr} from a slope sensor 89. The main electronic control unit 70 outputs switching control signals to the switching elements included in the inverter circuit 24 via its output port.

25 The following describes the operations of the vehicle 20 of the embodiment constructed as discussed above, especially

a series of operations in the event of the occurrence of a slip due to the spin of the drive wheels 62a and 62b during a run of the vehicle 20 on an ascending slope. Fig. 2 is a flowchart showing a drive control routine executed by the main control unit 70 in the vehicle 20 of the embodiment. This routine is carried out repeatedly at preset time intervals (for example, 8 msec).

When the drive control routine starts, the CPU 72 of the main electronic control unit 70 first inputs various data required for control, that is, the accelerator opening Acc from the accelerator pedal position sensor 84, the vehicle speed V from the vehicle speed sensor 88, a revolution speed Nm of the drive shaft 28, the gearshift position SP from the gearshift position sensor 82, and the brake pedal position BP from the brake pedal position sensor 86 (step S100). In this embodiment, the input of the revolution speed Nm of the drive shaft 28 is calculated from the rotational position θ_{res} detected by the rotational position detection sensor 32.

The routine then sets a motor torque T_m^* , which is to be output from the motor 22, based on the inputs of the accelerator opening Acc and the vehicle speed V (step S102). In the structure of this embodiment, variations in motor torque T_m^* against the accelerator opening Acc and the vehicle speed V are specified in advance and are stored as a map in the ROM 74. The procedure of the embodiment reads and sets the motor torque T_m^* corresponding to the given accelerator opening Acc

and the given vehicle speed V from the stored map. Fig. 3 shows one example of this map.

The routine subsequently calculates an angular acceleration α of the drive shaft 28 from the inputs of the revolution speed N_m (step S104). The angular acceleration α is computed by subtracting a previous revolution speed N_m input in the previous cycle of this routine from a current revolution speed N_m input in the current cycle of this routine (current revolution speed N_m - previous revolution speed N_m). The unit of the angular acceleration α in this embodiment is [rpm / 8 msec], as the revolution speed N_m is expressed by the revolutions per minute [rpm] and the time interval of execution of this routine is 8 msec. Any other suitable unit may be adopted to express the angular acceleration as a time variation in angular velocity. With a view to reducing a potential error, the angular acceleration α may be the average of current and past data of the angular acceleration calculated in the current and several past cycles (for example, three past cycles) of this routine.

After calculation of the angular acceleration α , the routine determines whether a slip occurs due to the spin of the drive wheels 62a and 62b (that is, the occurrence or non-occurrence of a slip or the convergence or non-convergence of a slip), based on the calculated angular acceleration α (step S106). The occurrence or non-occurrence of a slip may be specified by determining whether the angular acceleration α

exceeds a predetermined threshold. The convergence or non-convergence of a slip may be specified by determining whether the angular acceleration α falls to a negative value or whether the angular acceleration α remains negative for a
5 preset time period. Another technique may be adopted for such determination.

In the case of the occurrence of a slip, the routine restricts the motor torque T_m^* set at step S102 (step S108). Restriction of the motor torque T_m^* may subtract a fixed value
10 from the motor torque T_m^* or may subtract a varying value, which increases with an increase in degree of the slip, for example, an increase in angular acceleration α , from the motor torque T_m^* . Any other suitable method may be applied to attain the restriction.

15 After the restriction of the motor torque T_m^* , the routine successively determines whether the current gearshift position SP is in a forward drivable range, that is, in either a D range or a B range (step S110), whether a balancing torque T_{grad} corresponding to the road surface gradient is not less
20 than a predetermined level regarded as an ascending slope (step S112), and whether the vehicle runs in a reverse direction against the current gearshift position SP in the forward direction, that is, whether a slip-down of the vehicle is detected (step S114). In this embodiment, the balancing
25 torque T_{grad} is set according to a balancing torque setting routine shown in the flowchart of Fig. 4. As shown in Fig.

4, in the case of the non-occurrence of a slip and the vehicle speed V not equal to zero (steps S150 and S152), the balancing torque T_{grad} is set according to Equation (1) given below as a torque balancing with a force generated by the weight of the vehicle to act in a direction along the road surface gradient (step S154). The term 'Previous T_m^* ' in Equation (1) represents the motor torque T_m^* used as the torque output to the drive shaft 28 at step S130 in the previous cycle of the routine of Fig. 2. 'K1' denotes a constant specified according to the vehicle weight and the diameter of the wheels.

$$T_{grad} = \text{Previous } T_m^* - K1 \cdot \alpha \quad (1)$$

When the results of the successive determination at steps S110 to S114 show that the current gearshift position SP is in either the D range or the B range, that the balancing torque T_{grad} is not less than the predetermined level, and that the vehicle runs in the reverse direction, the routine sets a reflection ratio β based on the input vehicle speed V (step S116). In the structure of this embodiment, a variation in reflection ratio β against the vehicle speed V is specified in advance and is stored as a map in the ROM 74. The procedure of this embodiment reads and sets the reflection ratio β corresponding to the given vehicle speed V from the stored map. Fig. 5 shows one example of this map. In the illustrated example, the reflection ratio β is regulated to proportionally

increase from a value '0' to a value '1.0' during a rise of the vehicle speed V in the reverse direction from zero to a preset vehicle speed and to be kept at the value '1.0' after the vehicle speed V reaches the preset vehicle speed. After
5 setting the reflection ratio β , the routine calculates a brake torque T_{b*} from the balancing torque T_{grad} , the torque output to the drive shaft 28 (Previous T_{m*}), and the reflection ratio β according to Equation (2) given below (step S118). Here the brake torque T_{b*} represents a torque to be applied by the
10 hydraulic brakes 56a and 56b attached to the driven wheels 64a and 64b, which are different from the drive wheels 62a and 62b linked with the drive shaft 28 with the motor 22. In Equation (2), 'K2' denotes a conversion coefficient to convert a torque on the drive shaft 28 into a torque on the shaft of the driven
15 wheels 64a and 64b. As clearly understood from Equation (2), the brake torque T_{b*} is set as the product of a torque insufficiency relative to the balancing torque T_{grad} due to the restriction of the motor torque T_{m*} at step S108 and the reflection ratio β . As mentioned above, the reflection ratio
20 β is kept at the value '1.0' after the vehicle speed V in the reverse direction reaches the preset vehicle speed. The velocity of the slip-down of the vehicle thus converges to a value close to the preset vehicle speed.

$$25 \quad T_{b*} = K2 \cdot \beta \cdot (T_{grad} - \text{Previous } T_{m*}) \quad (2)$$

After setting the brake torque Tb^* , the routine successively executes a rate process of the brake torque Tb^* to attain a smooth increase or decrease in brake torque (step S120) and a guard process to guard the brake torque Tb^* with an upper limit torque Tb_{max} (step S122). Here the rate used in the rate process may be set equal to 32 Nm / 16 msec for the increase in brake torque and 32 Nm / 65 msec for the decrease in brake torque. The upper limit torque Tb_{max} used in the guard process may be set as a torque preventing a slip-down of the vehicle with two occupants on an ascending slope of approximately 14%.

When it is determined at step S106 that no slip occurs, when it is determined at step S110 that the gearshift lever 81 is not positioned in the forward drivable range, when it is determined at step S112 that the balancing torque T_{grad} is less than the predetermined level, or when it is determined at step S114 that the vehicle does not run in the reverse direction, the routine specifies no requirement for application of a brake torque by the hydraulic brakes 56a and 56b and sets the value '0' to the brake torque Tb^* (step S124).

The routine subsequently determines whether the driver is stepping on the brake pedal 85, based on the current brake pedal position BP input at step S100 (step S126). When it is determined that the driver is stepping on the brake pedal 85, the routine resets the brake torque Tb^* corresponding to the current brake pedal position BP for reflection of the driver's

requirement, regardless of the setting of the brake torque T_{b^*} at step S118 or at step S124 (step S128).

After setting of the motor torque T_{m^*} and the brake torque T_{b^*} , the routine drives and controls the motor 22 with the motor torque T_{m^*} , while sending the brake torque T_{b^*} to the brake ECU 50 to actuate and control the brake actuator 52 (step S130). The drive control routine is here terminated. The motor 22 is driven and controlled by outputting the switching control signals to the switching elements included in the inverter circuit 24. The brake ECU 50 receiving the input of the brake torque T_{b^*} outputs a control signal to the brake actuator 52 to actuate and control the brake actuator 52.

As one example, it is assumed that a slip occurs during a run of the vehicle on an ascending slope with the gearshift lever 81 positioned in the D range. In this case, the motor torque T_{m^*} required by the driver is restricted at step S108. When the restriction causes an insufficiency of the motor torque T_{m^*} relative to the road surface gradient (the balancing torque T_{grad}) in the course of convergence of the slip, a reverse run of the vehicle (a slip-down of the vehicle) is detected at step S114. In response to the detection, the brake torque T_{b^*} is set to make the vehicle speed converge to the preset vehicle speed according to the balancing torque T_{grad} and the vehicle speed in the reverse direction. The brake torque T_{b^*} is accordingly applied by the hydraulic brakes 56a and 56b on the driven wheels 64a and 64b, which are different

from the drive wheels 62a and 62b with the torque output from the motor 22. This enables the velocity of the slip-down of the vehicle to converge to the preset vehicle speed.

As described above, in the vehicle 20 of the embodiment,
5 in the event of a slip-down of the vehicle under restricting the output torque from the motor 22 due to the occurrence of a slip of the vehicle running on an ascending slope, the brake torque T_b^* generated by the hydraulic brakes 56a and 56b is applied to make the velocity of the slip-down of the vehicle
10 converge to the preset vehicle speed. The brake torque T_b^* generated by the hydraulic brakes 56a and 56b is set according to the balancing torque T_{grad} corresponding to the road surface gradient. This technique thus ensures practically constant drive feeling, regardless of the road surface gradient. The
15 brake torque T_b^* is applied to the driven wheels 64a and 64b, which are different from the drive wheels 62a and 62b with the torque output from the motor 22. This effectively prevents the brake torque from interfering with the output torque of the motor 22.

20 The vehicle 20 of the embodiment sets the balancing torque T_{grad} corresponding to the road surface gradient according to the relation between the angular acceleration α and the output torque from the motor 22, and calculates the brake torque T_b^* from the setting of the balancing torque T_{grad} .
25 One modified procedure may directly measure the road surface gradient with the slope sensor 89 and set the brake torque T_b^*

according to the observed road surface gradient.

The vehicle 20 of the embodiment sets the reflection ratio β based on the vehicle speed V in the reverse direction and calculates the brake torque T_{b^*} from the balancing torque T_{grad} , the torque output to the drive shaft 28, and the reflection ratio β . One modified procedure may directly set the brake torque T_{b^*} based on the vehicle speed V in the reverse direction, the balancing torque T_{grad} , and the torque output to the drive shaft 28.

The vehicle 20 of the embodiment sets the reflection ratio β based on the vehicle speed V in the reverse direction and multiplies the difference between the balancing torque T_{grad} and the torque output to the drive shaft 28 by the setting of the reflection ratio β to set the brake torque T_{b^*} . The velocity of the slip-down of the vehicle in the occurrence of a slip on an ascending slope thus converges to the preset vehicle speed. The brake torque T_{b^*} may otherwise be set by feedback control to make the velocity of the slip-down of the vehicle converge to the preset vehicle speed.

The embodiment discussed above regards the vehicle 20 equipped with the motor 22 that is mechanically connected to directly output power to the drive shaft linked with the drive wheels 62a and 62b. The technique of the invention may be applied to any vehicle equipped with a power output device that is capable of outputting power to a drive shaft. For example, the technique of the invention is applicable to a series hybrid

vehicle including an engine, a generator that is linked with an output shaft of the engine, and a motor that utilizes a supply of electric power from the generator to output power to a drive shaft. The technique of the invention is also applicable to

5 a mechanical distribution-type hybrid vehicle 120 of Fig. 6 including an engine 122, a planetary gear unit 126 that is linked with the engine 122, a motor 124 that is connected with the planetary gear unit 126 and generates electric power, and a motor 22 that is connected with the planetary gear unit 126

10 and is mechanically linked with a drive shaft connecting with drive wheels 62a and 62b to output power to the drive shaft. The technique is further applicable to an electrical distribution-type hybrid vehicle 220 of Fig. 7 including an engine 222, a motor 224 that has an inner rotor 224a linked

15 with an output shaft of the engine 222 and an outer rotor 224b attached to a drive shaft connecting with drive wheels 62a and 62b and relatively rotates through electromagnetic functions of the inner rotor 224a to the outer rotor 224b, and a motor 22 that is mechanically linked with the drive shaft to output

20 power to the drive shaft. The technique is also applicable to a hybrid vehicle 320 of Fig. 8 including a motor 22 that is linked via a transmission 324 (for example, a continuously variable transmission or an automatic step transmission) with a drive shaft connecting with drive wheels 62a and 62b, and

25 an engine 322 that is linked with a rotating shaft of the motor 22 via a clutch CL. In the event of the occurrence of a slip

on the drive wheels, the control procedure mainly controls the motor mechanically linked with the drive shaft by taking into account its quick output response and thereby restricts the torque output to the drive shaft. Control of another motor
5 and control of the engine may be carried out in cooperation with the control of this motor.

The embodiment discussed above is to be considered in all aspects as illustrative and not restrictive. There may be many modifications, changes, and alterations without
10 departing from the scope or spirit of the main characteristics of the present invention.

Industrial Applicability

The technique of the invention is applicable to
15 industries relating to vehicles like automobiles and train cars.
